Exercise 1 – Fourier spectrum

a. The build in functions fft2 and fftshift are used to create the Fourier spectrum image centered around the DC component of the Fourier transform. Some extra code is added for calculating the average of the image, which will be explained in more detail in part c of this exercise. To be able to view the spectrum, the values need to be scaled. So the log is taken of each value to increase the constrast.

```
% Read the image
  x = imread('../images/characters.tif');
   % Get image width and heigt
   [width, height] = size(x);
  % Perform the Fourier transform
  spectrum = fftshift(fft2(x));
  % Calculate the avarge of the image
  % It can be found by taking the dc component (center of the image)
  % And dividing it by the number of pixels
avg_fourier = abs(spectrum(width/2+1,height/2+1))/(width*height)
avg_mean = mean(mean(x))
13 % calculate the magnitude
spectrum = abs(spectrum);
16 % take the log value for better scaling in octave
17 logspectrum = log2(spectrum);
18 % Take note of max and min of the spectrum for image scaling
19 maxs = max(max(logspectrum));
20 mins = min(min(logspectrum));
  % Scale the image for output to file
  spectruming = uint8(floor((logspectrum - mins) / (maxs-mins) * 256));
   imwrite(spectruming, 'spectrum.png');
   % Show the log image as a figure
  figure, imshow(logspectrum,[]), colormap gray
```

b. The spectrum can be seen in figure 2.

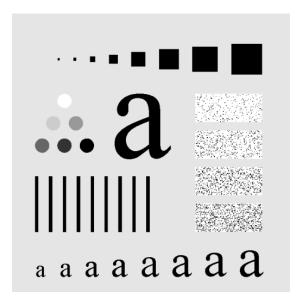

Figure 1: Original image

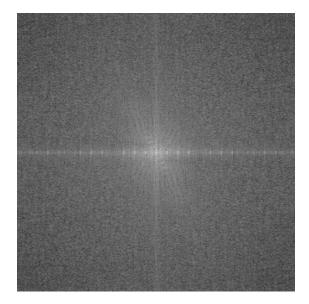

Figure 2: Fourier spectrum of figure 1

c. The magnitude of the center of the image is the DC component. For images, this is the sum of the grey levels of all pixels. Dividing this by the number of pixels gives the average grey level. In this case: 207.31 for figure 1. This value is equal to the result achieved by using mean two times.

Exercise 2 – Highpass filtering in the frequency domain

a. The Gaussian highpass transfer function is given by

$$H(u,v) = 1 - e^{-\frac{D(u,v)^2}{2 \cdot D_0^2}} = 1 - e^{-\frac{(u-P/2)^2 + (v-Q/2)^2}{2 \cdot D_0^2}}$$

where $P \ge 2 \cdot M - 1$, $Q \ge 2 \cdot N - 1$, u = [0, P - 1] and v = [0, Q - 1]. This function is used to lessen the strength of low frequencies in a spectrum by multiplying it elementwise with said spectrum. An example can be seen in Figure 3. Note that the white part allow the frequencies to pass through, while the black part weakens low frequencies if the spectrum is centered.

Figure 3: The Gaussian highpass filter with $D_0 = 30$

Another thing to note is that filter size is bigger than the image size. The reason for this is that the image is expected to be padded to prevent wraparound errors as shown in Figure 4.32 in the book.

```
function H = IPgaussian (D0, M, N)

// calculate the padded image dimensions based on the suggested value

// in Section 4.7.3 of the book

P = 2 * M;

Q = 2 * N;

// take u = 0, ..., P-1 and v = 0, ..., Q-1 (book Section 4.8.0)

[V, U] = meshgrid(0:P-1, 0:Q-1);

// calculate the squared distance D(u,v) of Eq. (4.8-2)

squaredist = ((U - P/2).^2 + (V - Q/2).^2);

// calculate H(u,v) based on Eq. (4.9-4)

// note that this is done with matrix operations

Hc = ones(P, Q) - e.^(- squaredist / (2 * D0^2));

// finally the filter is uncentered

H = ifftshift(Hc);
endfunction
```

- **b**. The general way of applying filters in the frequency domain is summarized in Section 4.7.3 of the book. In the case of IPftfilter the steps are as follows:
 - Step 1 Pad the image to the size of the filter to prevent wraparound errors.
 - Step 2 Perform DFT on this padded image to get the spectrum.
 - Step 3 Apply the given filter to the spectrum.
 - Step 4 Perform the inverse DFT on the new spectrum and take the real parts.
 - Step 5 Extract the final image by removing the padding.

Note that this can also be done with every spectrum shifted to the center. This does not influence the result, so it was omited.

```
function rval = IPftfilter (x, H)
   M = size(x, 1);
3
  N = size(x, 2);
  % pad the image such that it has the same dimensions
  % as the filter transfer function
  fp = uint8(zeros(size(H)));
  fp(1:M, 1:N) = x;
11 fp = im2double(fp);
12 % calculate the spectrum of the padded image
^{13} % note that shifting the center is not needed, because the filter H
      is also
14 % not centered
15  Fp = fft2(fp);
16 % applay the filter to the image
_{17} G = H .* Fp;
_{\rm 18} % convert the new spectrum to the image by taking the inverse DFT,
      the real
  % values and unpadding it
  newx = real(ifft2(G))(1:M, 1:N);
  rval = im2uint8(newx);
21
   endfunction
```

c. The results can be seen in figure 4

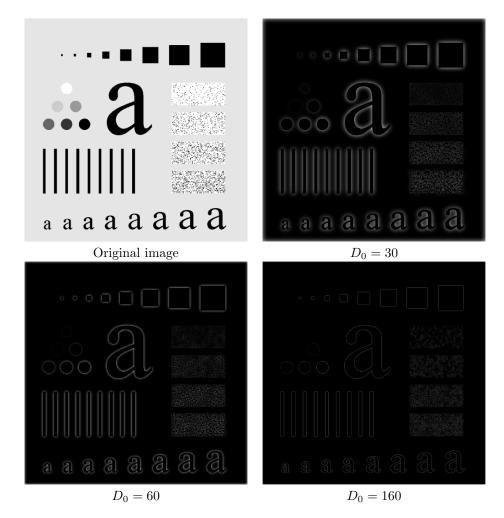

Figure 4: Gaussian Highpass Filtering

Exercise 3 – Median filtering

a. The IPmedian function takes the distorted image and a value k as its input parameters. The for each pixel in the image, a window is created with width and height of 2k + 2. When encountering a boundary, the windowsize is decreased to fit the image. A submatrix is then used to represent all the pixels in the window. From this submatrix, the median is calculated and used for the output image.

```
\% Median filter width a 2k+1 x 2k+1 window
  function [out] = IPmedian(img,k)
   % get the image size
  [width, height] = size(img)
  %create the output image
  dest = uint8(zeros(size(img)));
   % loop over all pixels
   for x = 1 : width
     for y = 1: height
       \% determine the edge of the window
       \% the size of the window shrinks at the boundaries of the image
12
       startx = max(x-k,1);
13
       starty = max(y-k,1);
14
       endx = min(x+k, width);
15
       endy = min(y+k,height);
16
       % get the submatrix
17
       submat = img(startx:endx,starty:endy);
18
       [w,h] = size(submat);
19
       \% convert it to a vector to be able to calculate the median
20
       submat = reshape(submat, 1, w*h);
       \% take the median and store it
       dest(x,y) = median(submat);
23
24
     end
   end
25
   % output the image
   out = dest;
```

b. The image original image (5) and the image distorted by noise (6).

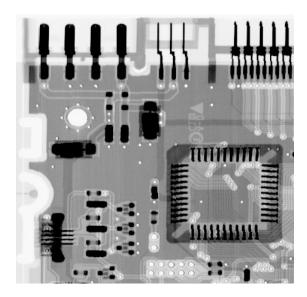

Figure 5: Original image of the circuitboard

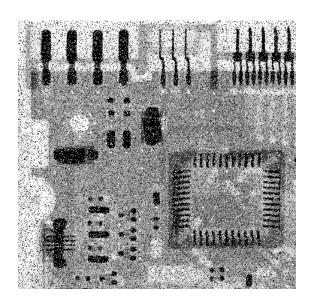

Figure 6: Figure 5 with salt & pepper noise with Pa=Pb=0.2

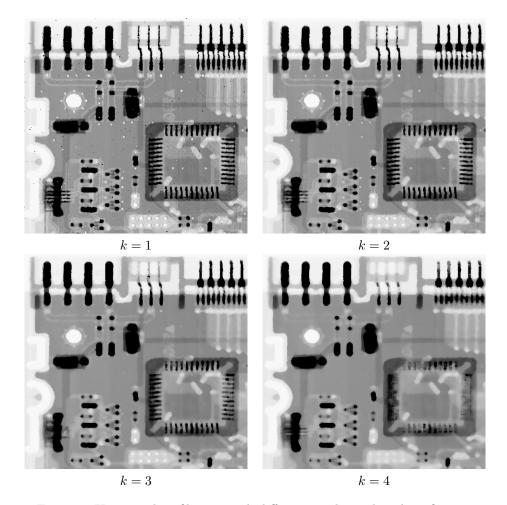

Figure 7: Using median filtering with different window values k on figure 6

c. In the image created by filtering with k=1, some noise is still present. This is equal to the image 5.10b in the book. Using k=2 removes all noise particles. Increasing k further reduces the sharpness of the image as can be seen in the two lower images in figure 7.
